

## **BIOSTATISTICS**

### **TOPIC 11: ESTIMATION OF SAMPLE SIZE**

The design of an experiment is essentially a plan for collecting information, which, like any other commodity, may be acquired at varying prices, depending on the manner in which the data are obtained. Some measurements contain a large amount of information concerning the parameter of interest; others may contain little or none. Since the product of research is information, we want to make its "purchase" at minimum cost.

The sampling procedure, or experimental design as it is usually called, affects the quantity of information per measurement. This, along with the sample size  $n$ , controls the total amount of relevant information in a sample. With few exceptions, we shall be concerned with the simplest sampling situation, random sampling from a relatively large population, and will devote our attention to the selection of sample size,  $n$ .

The investigator makes little progress in planning an experiment before encountering the problem of selecting the sample size. Indeed, perhaps one of the most frequent questions asked of the statistician is: "how many measurements should be included in the sample?". Unfortunately, the statistician can not answer this question without knowing how much information the experimenter wishes to collect. Certainly, the total amount of information in the sample will affect the measure of goodness of the method of inference and must be specified by the investigator. Referring specifically to estimation, we would like to know how accurate the investigator wishes the estimate to be. This may be stated by specifying a bound on the error of estimation.

#### **THE LOGIC OF STATISTICAL SIGNIFICANCE**

In previous topics, we have learned several statistical procedures used to test the numerical "significance" of an observed difference between groups. The calculations used for the procedures depend on the kind of basic data in which the results were expressed. For dimensional data, the results would be cited as mean and the usual statistical procedure would be the t-test. For nominal data, the results are expressed as frequency counts or proportions, percentages or rates; and the usual statistical procedure would be a Chi square test. If the data are expressed in rank ordinal values, the usual statistical procedure would be the Wilcoxon rank sum test or the Mann-Whitney U test.

Although each of these tests is chosen according to the type of data under examination, the underlying logic is identical. It follows the same principle that was used to prove theorems in school geometry. We assume that a particular conjecture is true. We then determine the consequences of that conjecture. If the consequences produce an obvious absurdity or implausibility, we conclude that the original conjecture can not be true, and we reject it as false.

When this reasoning is used for the statistical strategy that is called "**hypothesis testing**", the argument proceeds as follows. We have observed a difference, called  $\delta$ , between groups A and B. To test its "statistical significance", we assume, as a conjecture, that groups A and B are actually not different. This conjecture is called **null hypothesis** and is usually denoted by  $H_0$ . With this assumption, we then determine how often a difference as large as  $\delta$ , or even larger, would arise by chance from data for two groups having the same number of subjects as A and B. The result of this determination is the **P value** that emerges from the statistical test procedure.

To draw statistical conclusions, we must establish a concept that was not necessarily for the inferential reasoning of school geometry. This concept is called an  **$\alpha$  level of significance**. It is used to demarcate the **rejection zone**. If the P value that emerges from the statistical test is equal to or smaller than  $\alpha$ , we decide that we shall reject the null hypothesis. In doing so, we demarcate  $\alpha$  as the risk of being wrong in this conclusion - but it is a risk we must take in order to have a statistical mechanism for drawing conclusions. In geometrical inference,  $\alpha$  is always 0. In statistical inference,  $\alpha$  is usually chosen to be 0.05 (or 5%) or 1 in 20, although some investigators may select other boundaries such as 0.1 or 0.01.

The  $\alpha$  level is analogous to the risk of getting a **false positive** result in a diagnostic test. Suppose that we make a diagnosis of lung cancer after finding a positive result in the Pap smear of a patient. If the patient does in fact have lung cancer, the diagnostic decision is correct - a true positive. If the patient does not have a lung cancer, the diagnosis is wrong - a false positive conclusion. The  $\alpha$  level indicates the statistical risk that this decision may be wrong and that there is actually no difference between the groups. Statisticians refer to this error as **type I error**. The value  $1-\alpha$  can therefore be viewed as the **specificity** of a diagnostic test, which is the likelihood that the test will have a negative result when the disease is absent. The value of  $1-\alpha$  denotes the likelihood of being correct when we do not reject the null hypothesis and thereby conclude that the observed difference is not "statistically significant".

All of the strategies described constitute a long-standing, well established statistical procedure that is still used by many investigators as the natural way to calculate test statistic. In 192, Jerzy Neyman and Egon S. Pearson pointed out that the reasoning was incomplete. According to Neyman-Pearson argument, a statistical test of significance, like a medical test of diagnosis, has another side to it. In diagnosis, when thinking about the situation where the disease is absent, we recognise that a diagnostic test will yield either a false positive diagnosis or a true positive, but what about the situation where the disease is actually present? We thus have far ignored this side of diagnostic reasoning. What about the **false negative** or **true positive** diagnoses that will occur if the disease actually exists? In statistical reasoning, the counterpart to a false negative diagnosis is the error we make if we conceded the null hypothesis and concluded that the observed difference was not statistically significant when, in fact, an important difference exists. If the true difference is important and if we fail to draw that conclusion, we would make an erroneous decision. This type of false negative is what statistician call a **type II error**. Thus, if  $1-\alpha$  corresponds to **specificity** of a diagnostic test,  $1-\beta$  corresponds to its **sensitivity** - the likelihood of making a positive conclusion when it is true.

#### ANALOGY OF CONCLUSIONS IN DIAGNOSTIC AND STATISTICAL REASONING

##### (a) Diagnostic reasoning

		Disease is really	
		Present	Absent
Test result	Positive	True positive	False positive
	Negative	False negative	True negative

##### (b) Statistical reasoning

		Significant difference is	
		Present ( $H_0$ not true)	Absent ( $H_0$ true)
Statistical test result	Reject $H_0$	No error;	Type I error;
		$1 - \beta$	$\alpha$
Accept $H_0$	Type II error;	No error;	

$\beta$

$1 - \alpha$

---

Although an investigator is free to set any boundary of error that makes sense, the usual values for type I and type II errors are 0.05 and 0.20, respectively. The reason is that in science, it is seen as less desirable to mistakenly reject a true  $H_0$  (which leads to false positive claims) than to mistakenly fail to reject  $H_0$  (which leads only to failure to find something and no claim at all).

In calculation of sample size, the investigator must specify the following information:

- (a) the parameter of major interest;
- (b) the bound of on the error of estimation (type I and type II error);
- (c) the difference of interest and its standard deviation.

We will illustrate the procedure of calculation by considering several examples as follows:

## I. SAMPLE SIZE FOR ESTIMATING A POPULATION PARAMETER

### 1.1 Determination of sample size for estimating mean of a population

Suppose it is desired to estimate, with a confidence interval, the mean of a population ( $\mu$ ). One of the first question arise is how large the sample should be? This question must be given serious consideration, because it is a waste of time and resources to take a larger sample than is needed to achieve the desired results. Similarly, a sample that is too small may lead to results that are of no practical value. The key questions are:

First, how close do we want our estimate to be to the true value? In other words, how wide would we like to make the confidence interval that we want to construct?

Second, how much confidence do we want to place in our interval? That is, what confidence coefficient do we wish to employ?

These questions bring to mind the nature of the confidence interval that will eventually be constructed. This interval will be of the form:

$$\bar{y} \pm z_{\alpha/2} \frac{\sigma}{\sqrt{n}}$$

where  $z_{\alpha/2} \frac{\sigma}{\sqrt{n}}$  is equal to one half the confidence interval. If question 1 can be answered, then the following equation can be set up:

$$d = z_{\alpha/2} \frac{\sigma}{\sqrt{n}} \quad [1]$$

where  $d$  indicates how close the true mean we want our estimate to be. That is,  $d$  is equal to one half the desired interval width. Equation 1 can be written another way which yields the required sample size:

$$N = \frac{(z_{\alpha/2})^2 \sigma^2}{d^2}$$

[2]

The value of  $z_\gamma$  for various  $\alpha$  levels is tabulated in Table 1. For example, for  $\alpha = 0.05$ ,  $z_\alpha = 1.96$  and  $z_{\alpha/2} = z_{0.025} = 1.96$ .

Table 1: Table of Normal deviates

$\alpha$	$Z_\alpha$	$Z_{\alpha/2}$
0.20	0.84	1.28
0.10	1.28	1.64
0.05	1.64	1.96
0.01	2.33	2.81

Example 1: Suppose that we wish to estimate the average height (denoted by  $\mu$ ) in a population, and we wish the error of estimation to be less than 2 cm with a probability of 0.95. Since approximately 95% of the sample means will lie within 1.96(SE) of  $\mu$  in repeated sampling, we are asking that 1.96(SE) equal 2 cm (See Figure 1). Then,

$$1.96(\text{SE}) = 2$$

or  $\frac{1.96\sigma}{\sqrt{n}} = 2 \quad (\text{since } \text{SE} = \frac{\sigma}{\sqrt{n}})$

$$\Rightarrow n = \left( \frac{1.96}{2} \right)^2 \sigma^2$$

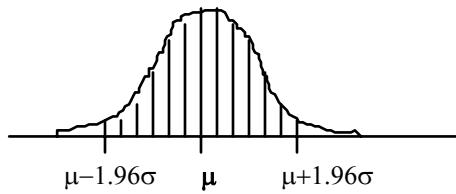

Figure 1. Approximate sampling distribution of  $\bar{y}$  for large samples

You should now note that we can not obtain a sample size  $n$  unless the population standard deviation is specified. This is certainly what we would expect, because the variability of  $\bar{y}$ , the sample mean, depends upon the variability of the population from which the sample was drawn.

In the above example, if the standard deviation of the population ( $\sigma$ ) is unknown, we may use the sample standard deviation ( $s$ ). Suppose that from previous study, the sample standard deviation was 10 cm, then the required sample size would be:

$$n = \left( \frac{1.96}{2} \right)^2 \sigma^2 = \left( \frac{1.96}{2} \right)^2 (10^2) \approx 100 .$$

## 1.2 Determination of sample size for estimating proportions

When a population proportion is to be estimated, the sample size is determined in essentially the same way as described above for estimating a population mean. Half the desired interval  $d$  is set to equal to the product of the reliability coefficient and the standard error. The assumption of random sampling and conditions warranting approximate normality of the distribution of  $\bar{p}$  (the sample proportion) lead to the following formula:

[3]

As can be seen, this formula requires a knowledge of  $p$ , the proportion of population with the characteristic of interest.

Example 2: We want to estimate the proportion of population whose VDR genotype is *tt*. We would like to estimate  $p$  to within 0.05 with 95% confidence interval. The proportion of population with *tt* in a normal population is 13%. Using these information, we obtain:

$$n = \frac{(1.96)^2(0.13)(0.87)}{(0.05)^2} = 174 \text{ subjects.}$$

### 1.3 Determination of sample size for estimating correlation coefficients

In observational studies which involve estimate a correlation ( $\rho$ ) between two variables of interest, say,  $X$  and  $Y$ , a typical hypothesis is of the form:

$$\begin{aligned} H_0: \rho &= 0 \\ \text{versus } H_1: \rho &\neq 0 \end{aligned}$$

That is, we are interested in testing a hypothesis of no relationship the two variables against an unspecified, but significant, relationship.

The test statistic is of the Fisher's z transformation, which can be written as:

$$t = \frac{1}{2} \log_e \left[ \frac{1+r}{1-r} \right] \sqrt{n-3}$$

where  $n$  is the sample size and  $r$  is the observed correlation coefficient. It can be shown that  $t$  is normally distributed with mean 0 and unit variance, and the sample size to detect a statistical significance of  $t$  can be derived as:

$$N = \frac{(z_\alpha + z_\beta)^2}{\frac{1}{4} \left[ \log_e \left( \frac{1+\rho}{1-\rho} \right) \right]^2} + 3 \quad [4]$$

For instance, the sample size required to detect a correlation coefficient of 0.5 at the significance level of 5% ( $\alpha = 0.05$ ) and power 80% ( $\beta = 0.2$ ) is:

$$N = \frac{(1.64 + 0.84)^2}{\frac{1}{4} \left[ \log_e \left( \frac{1+0.5}{1-0.5} \right) \right]^2} + 3 \cong 23 \quad //$$

## II. TWO PARALLEL GROUPS

### 2.1 Determination of sample size for testing differences between means

Consider the one-sided significance test for comparing the means  $\mu_1$  and  $\mu_2$  of  $X_1$  and  $X_2$ , respectively, where  $X_1$  and  $X_2$  are two random variables representing the endpoint in the two groups. To test:

$$H_o: \mu_1 = \mu_2$$

$$H_1: \mu_1 = \mu_2 + \Delta$$

Let  $n_1$  and  $n_2$  be the sample sizes for groups 1 and 2, respectively;  $N = n_1 + n_2$  be the total sample size, and  $r = \frac{n_1}{n_2}$  be the ratio of sample sizes in first and second groups. Also, let  $\sigma$  be the common standard deviation of  $X_1$  and  $X_2$ , and  $z_\gamma$  be the value from tables of cumulative normal distributions, i.e.  $P(Z < z_\gamma) = 1 - \gamma$  for a standard normal,  $Z$

$$\begin{aligned}\alpha &= P(\text{type I error}) \\ &= P(\text{reject } H_o \mid H_o \text{ is true}) \\ &= \text{size of test}\end{aligned}$$

$$\begin{aligned}\beta &= P(\text{type II error}) \\ &= 1 - P(\text{reject } H_o \mid H_1 \text{ is true}) \\ &= 1 - (\text{Power of test})\end{aligned}$$

Assuming that  $X_1$  and  $X_2$  are normally distributed, then the required total sample size is given by:

$$N = \frac{(r+1)^2(z_\alpha + z_\beta)^2 \sigma^2}{r\Delta^2}$$

Note that the difference  $\Delta$  can also be expressed in terms of the standard deviation  $\sigma$  (as a Z score) by:

$$Z = \frac{\Delta}{\sigma}$$

then, the above formula becomes:

$$N = \frac{(r+1)^2(z_\alpha + z_\beta)^2}{rZ^2} \quad [5]$$

Tabulation of this formula is given in Table 1 in the appendix section. Note that in this table, **N1:N2** is equivalent to  $r$  of equation [5].

This is the formula used in many introductory texts. It rejects  $H_0$  whenever the difference between means is large in *either* direction.

### Evaluation of power

These basic formulae can be used to estimate the smallest difference which can be detected ( $\Delta$ ) or the power of a study which has been performed. For example, using [5], we can also write:

$$\Delta = \frac{(r+1)(z_\alpha + z_\beta)\sigma}{\sqrt{rN}}$$

or

$$z_\beta = \frac{\Delta\sqrt{rN}}{\sigma(r+1)} - z_\alpha \quad [6]$$

## 2.2 Determination of sample size for testing differences between two proportions

Let  $\pi_1$  and  $\pi_2$  be the proportions with the endpoint of interest in the two population. The usual null and alternative hypothesis could be stated as:

$$H_o: \pi_1 = \pi_2$$

$$H_1: \pi_1 = \pi_2 + \Delta \quad \text{or} \quad H_1: \frac{\pi_1}{\pi_2} = R$$

In practice, we do not know  $\pi_1$  and  $\pi_2$ , but have to estimate them from sample data. Let  $p_1$  and  $p_2$  be the two respective estimates from two samples of populations, then the test of whether  $\pi_1$  and  $\pi_2$  are different is given by the well-known statistic:

$$T = \frac{p_1 - p_2}{K}$$

which, in this case, arising from a normal approximation to a binomial.

where  $K = \sqrt{p(1-p)\left(\frac{1}{n_1} + \frac{1}{n_2}\right)}$

and  $p = \frac{n_1 p_1 + n_2 p_2}{n_1 + n_2}$  is the average proportion of the two samples.

For a one-sided test of size  $\alpha$  and power  $1-\beta$ , reject  $H_0$  if  $T > z_\alpha$  such that  
 $P(T > z_\alpha | H_1 \text{ true}) = 1 - \beta$ .

Now, when  $H_1$  is true  $\frac{p_1 - p_2 - (R-1)\pi}{\sqrt{\frac{R\pi(1-R\pi)}{n_1} + \frac{\pi(1-\pi)}{n_2}}}$  is normally distributed with mean 0

and variance of 1.

$$\text{Let } K_1 = \sqrt{\frac{R\pi(1-R\pi)}{n_1} + \frac{\pi(1-\pi)}{n_2}},$$

then:

$$\begin{aligned} P(T > z_\alpha | H_1 \text{ true}) &= P\left\{\frac{p_1 - p_2 - (R-1)\pi}{K_1} > z_\alpha \frac{K}{K_1} - \frac{(R-1)\pi}{K_1} | H_1 \text{ true}\right\} \\ &= P\left(Z > \frac{z_\alpha K - (R-1)\pi}{K_1}\right) \\ &= 1 - \beta \end{aligned}$$

$$\Rightarrow z_\alpha K - (R-1)\pi = z_{1-\beta} K_1 = -z_\beta K_1$$

$$\Rightarrow z_\alpha K + z_\beta K_1 = (R-1)\pi$$

Substituting for  $K$  and  $K_1$  and rearranging gives:

$$N = \frac{r+1}{r(R-1)^2 \pi^2} [z_\alpha \sqrt{(r+1)p(1-p)} + z_\beta \sqrt{R\pi(1-R\pi) + r\pi(1-\pi)}]^2 \quad [7]$$

Now  $p$  is unknown in advance, but a reasonable approximation may be obtained by assuming that  $p_1$  and  $p_2$  take their population values under  $H_1$ , i.e.  $R\pi$  and  $\pi$ , respectively.  
Thus:

$$p \approx \frac{n_1 R \pi + n_2 \pi}{n_1 + n_2} = \frac{\pi(rR + 1)}{r + 1}$$

Tabulation of this formula is given in Table 2 in the appendix section. Note that in this table, **RR** (the relative risk) is equivalent to  $R$  of equation [7], **P** is equivalent to  $\pi$  of equation [7] and **N1:N2** is equivalent to  $r$  in the equation.

### Evaluation of power

For a given value of  $R$ ,  $r$  and  $\pi$ , we can evaluate the power of a study by using the following formula:

$$z_\beta = \frac{\pi(|R - 1|)\sqrt{rN} - z_\alpha(r + 1)\sqrt{p(1-p)}}{\sqrt{(r+1)[R\pi(1-R\pi) + r\pi(1-\pi)]}} \quad [8]$$

### 2.3 Determination of sample size for case-control studies

In a case control study, data are often summarised by an odds ratio or relative risk, rather than a difference between proportions. If  $p_1$  is the proportion of cases exposed to a risk factor and  $p_2$  is the proportion of controls exposed to the same risk factor, then the odds ratio of being a case given the risk factor is odds ratio (OR)

$$\text{OR} = \frac{p_1(1-p_2)}{p_2(1-p_1)}$$

An approximate sample size formula for this design is:

$$N = \frac{(1+r)^2(z_{\alpha/2} + z_\beta)^2}{r(\ln \text{OR})^2 \bar{p}(1-\bar{p})} \quad [9]$$

Tabulation of this formula is given in Table 3 in the appendix section. Note that in this table, **P** is equivalent to  $\bar{p}$  of equation [9] and **N1:N2** is equivalent to  $r$  in the equation.

## 2.4 Determination of sample size for testing differences between two correlation coefficients

In detecting a relevant difference between two correlation coefficients  $r_1$  and  $r_2$  obtained from two independent samples of sizes  $n_1$  and  $n_2$ , respectively, we need to firstly transform these coefficients into z value as follows:

$$z_1 = \frac{1}{2} \log_e \left[ \frac{1+r_1}{1-r_1} \right]$$

and 
$$z_2 = \frac{1}{2} \log_e \left[ \frac{1+r_2}{1-r_2} \right]$$

These two statistics have variances equal to  $\frac{1}{n_1 - 3}$  and  $\frac{1}{n_2 - 3}$ , respectively.

To test the hypothesis of

$$H_o: \rho_1 = \rho_2$$

against  $H_1: \rho_1 \neq \rho_2$

we use the statistic:

$$t = \frac{z_1 - z_2}{\sqrt{\frac{n_1 + n_2 - 6}{(n_1 - 3)(n_2 - 3)}}}$$

which is normally distributed with mean 0 and unit variance.

With a specification of power  $1-\beta$ , the above equation can be solved for total sample size  $N$  as follows:

$$N = \frac{4(z_\alpha + z_\beta)^2}{(z_1 - z_2)^2} \quad [10]$$

For instance the sample size required to detect a difference between two correlation coefficients of 0.4 and 0.8 at the significance level of 5% (two-tailed) test and 90% power can be calculated as follows:

$$z(0.4) = \frac{1}{2} \ln\left(\frac{1+0.4}{1-0.4}\right) = 0.424$$

$$z(0.8) = \frac{1}{2} \ln\left(\frac{1+0.8}{1-0.8}\right) = 1.098$$

and  $N = \frac{4(1.96 + 1.28)^2}{(0.424 - 1.098)^2} = 92$  subjects or 46 in each group.

Full tabulation of sample size ( $N$ ) for various correlation coefficients based on formula [10] is given in Table 4. Note that in this table the ratio of sample size for group 1 to that of group 2 is assumed to be 1.

### III. MORE THAN TWO PARALLEL GROUPS

The determination of sample sizes required in the comparison of  $g$  groups when  $g > 2$  is far more complicated than the determination of sample sizes for the case  $g = 2$ . Consider first the comparison of  $g$  parallel groups with  $n$  subjects studied in each. Let  $\mu_1, \mu_2, \dots, \mu_g$  denote the  $g$  underlying means, let  $\sigma^2$  denote the assumed common underlying variance, and assume that the measurements in each group are independently and normally distributed. Under the statistical hypothesis that

$$H_0: \mu_1 = \mu_2 = \dots = \mu_g,$$

the ratio of mean squares from the analysis of variance table

$$F = \frac{BMS}{WMS}$$

has the so-called central F distribution. This distribution has two parameters, the number of degrees of freedom in the mean square between groups (BMS), say  $v = g - 1$ , and the number of degrees of freedom in the mean square within groups (WMS), say,  $u = g(n - 1)$ .

When the hypothesis is not true, meaning that at least two of the underlying means are unequal, the test statistic has a distribution, the non-central F distribution, which depends on a third quantity termed the non-centrality parameter:

$$\delta = \frac{\sqrt{n \sum (\mu_i - \bar{\mu})^2}}{\sigma}$$

where  $\bar{\mu} = \frac{1}{g} \sum \mu_i$ .

Let  $F_{v,u,\delta}$  denote a random variable having the non-central F distribution with df  $v, u$  and parameter  $\delta$ . A statistical statement of the problem of sample size determination is as follows. Let the significance level be  $\alpha$  as well as the value of the underlying variance  $\sigma^2$  and the values of the mean  $\mu_1, \mu_2, \dots, \mu_g$  which, if they indeed characterised the  $g$  groups, would be considered clinically significant that the chances should be  $1 - \beta$  of finding statistical significance. Significance would be declared if the ratio of MS exceeded the tabulated value of  $F_{v,u,\alpha}$  and the probability statement defining the power is:

$$P(F_{v,u,\delta} > F_{v,u,\alpha}) = 1 - \beta$$

Let  $F^* = F_{v,u,\alpha}$  and define:

$$\lambda = \frac{\sum (\mu_i - \bar{\mu})^2}{(g-1)\sigma^2}$$

a parameter whose value does not depend on  $n$ . The non-central parameter is obviously related to  $\lambda$  by means of the expression:

$$\delta^2 = n(g-1)\lambda$$

With the values of  $g, \lambda, \alpha$  and  $\beta$  specified, the required sample size per group,  $n$ , is such that the equation:

$$Z_\beta = \frac{1}{\sqrt{(g-1)(1+n\lambda)F^* + g(n-1)(1+2n\lambda)}} \\ \times \left( \sqrt{g(n-1)[2(g-1)(1+n\lambda)^2 - (1+2n\lambda)]} - \sqrt{F^*(g-1)(1+n\lambda)(2g(n-1)-1)} \right)$$

is approximately satisfied.

For  $g = 4$  groups, using  $\alpha = 0.05$  and assume that the value of the standard deviation within each group is  $\sigma = 3$ , and that the four means  $\mu_1 = 9.775, \mu_2 = \mu_3 = 12$  and  $\mu_4 = 14.225$ ,

represent such clinically significant that the power  $1 - \beta = 0.8$  when those are the underlying means, the value of  $\lambda = \frac{9.901}{3 \times 9} = 0.367$

You are required to verify that for  $n = 10$ ,  $F^* = F_{3,36,0.05} = 2.85$  and  $z_\beta = 0.712$ . For  $n = 11$ ,  $F^* = F_{3,40,0.05} = 2.83$ ,  $z_\beta = 0.873$ . Thus  $n = 11$  is the required sample size.

## IV. SOME COMMENTS

Some basic formulae for calculating sample sizes have been presented. It would be appropriate to summarise a few points here:

(a) In designing a study, an investigator must consider the issue of sample size. With respect to this, the investigator must specify four values: (i) the level of significance  $\alpha$  (type I error); (ii) the power ( $1-\beta$ ) of type II error; (iii) the difference of clinical significance to be detected and (iv) the (estimated) standard deviation for the significance test.

All of these values are interlinked:

(b) As have been implicitly assumed from these formulae, the larger the sample size, the larger the power.

(c) The larger the difference to be detected, the larger the power required. Large sample sizes will be needed in order to have a high power to detect a small difference.

(d) The larger the variability as represented by the standard deviation, the weaker the power.

(e) If  $\alpha$  is increased, power is increased ( $\beta$  is decreased). An increase in  $\alpha$  results in a smaller Z.

## V. EXERCISES

1. Refer to the Melhus et al study - ask to calculate power.
2. Refer to the Looney et al study - power ?
3. R Prince's study
4. Abstract in Wayne State University
4. How many subjects would you need to estimate a proportion of within  $\pm 5\%$  (95% confidence interval) if the expected proportion is 10% in the general population?
5. Two diets are to be compared with regard to weight gain of weaning rats. If the weight gains due to the diets differ by 10 g or more, we would like to be 80% sure that we obtain a significant results. How many rats should be in each group if the standard deviation is estimated to be 5 g and the test will be performed at 5% significance level.
6. An investigator hypothesises that the improvement rate associated with a placebo is 0.45 and that the improvement rate associated with an active drug is 0.65. He plans to perform a one-tailed test.
  - (a) If the desired significance level is 0.01 and a power of  $1 - \beta = 0.95$ , how large a sample per treatment must he study?
  - (b) How large must this sample sizes if he relaxes his significance level to 0.05 and power 0.80?
